Effects of Soil Moisture and Boundary Layer Parameterizations on Precipitation in Regional Climate Simulations over the Rocky Mountains and High Plains

M. Pagowski and G. A. Grell
NOAA Research/Earth System Research Laboratory, Boulder, Colorado, USA

1. Introduction

Regional climate simulations are performed in June 2004 with the WRF model to study the effects of soil moisture and boundary layer parameterizations on precipitation. Convection is parameterized in simulations on 5-km resolution grid with an ensemble of closure schemes based on varying assumptions (Grell and Devenyi 2002). Turbulence is parameterized with a 2.5 order closure (Mellor-Yamada-Janjic, Janjic, 2001, MYJ) and a bulk scheme (Yonsei University, Hong and Dudhia, 2004, YSU), and Noah (Ek et al., 2003) and RUCLSM (Smirnova et al., 2002) land surface models to calculate surface fluxes are used. Initial conditions for the atmospheric and the land surface models are obtained from the RUC analysis.

2. Observations

Accumulated precipitation in June 2004 using a .25 degree resolution CPC analysis (gauges) and STAGE4 data (radar and gauges) is presented in Figure 2.

3. Sensitivity Studies

Initial soil moisture obtained from the RUC analysis does not differ significantly from the minimum values allowed for a given soil type. Sensitivity of precipitation to the initial soil moisture is studied by assigning maximum soil moisture for a given soil type.
