CAMx was used to investigate the characteristics of O<sub>3</sub> production in MCMA during an “O<sub>3</sub>-South” episode by examining the relationship between O<sub>3</sub> formation and precursors, which are important to understand the photochemical processes of O<sub>3</sub> formation and develop effective control strategies. Model results exhibit a scatter relationship between the O<sub>3</sub> production and ambient NO<sub>x</sub> levels due to varying primary radical production under different NO<sub>x</sub> levels. High O<sub>x</sub> (O<sub>3</sub> + NO<sub>2</sub>) photochemical production rates of 10-80 ppb/hr are predicted due to the high reactivity of VOCs in which alkanes, alkenes, and aromatics exert comparable contributions. The predicted ozone production efficiency is between 4-10 O<sub>3</sub> molecules per NO<sub>x</sub> molecule oxidized, and increases with VOC-to-NO<sub>2</sub> reactivity ratio. Sensitivity studies suggest that O<sub>3</sub> formation in the MCMA urban region with less chemical aging (NO<sub>z</sub>/NO<sub>y</sub> < 0.4) is VOC-limited. Both the simulated behavior of O<sub>3</sub> production and its sensitivities to precursors suggest that mid-day O<sub>3</sub> formation during this episode is VOC sensitive in the urban region on the basis of the current emissions inventory.
